* Laboratory results can never be the only base of a medical report. The patient history and further tests have to be taken into account*
**Intended Use**

The Diagnostic Automation Microwell ELISA dengue fever test is a semi-quantitative enzyme immunoassay for the detection of antibodies to dengue, in samples of human serum. This test is intended to be performed by trained medical technologists only.

**Summary and Explanation**

Dengue fever, caused by any of the four serotypes of dengue virus is endemic in Southeast Asia and South and Central America. Repeat infection with a second type of dengue virus is thought to cause dengue hemorrhagic fever in about 10 percent of infected people. Dengue antibodies do not confer immunity beyond 3-6 weeks to a second dengue type.

Epidemiological factors, clinical findings (including fever, tachycardia, thrombocytopenia, etc.), exposure in endemic regions, and other laboratory results should be considered in diagnosing acute disease. Acute disease diagnosis will also include a positive laboratory confirmation in many cases.

Infection with dengue virus can result in a wide disease spectrum, from a mild fever to life-threatening dengue hemorrhagic fever and dengue shock syndrome (1). Symptoms of classical dengue fever, following a 5-8 day incubation period, include rash, severe headache, nausea, vomiting, chills, malaise, macular rash and may include lymphadenopathy. Hemorrhagic dengue fever involves increased blood vessel permeability which can lead to shock and death in about 10% of reported cases. Dengue fever can only be treated by supportive care and is prevented by mosquito control.

In primary infections, circulating IgM antibody to the viral coat proteins is detected 5-6 days after the onset of illness, and gradually decreases within 1-2 months of onset (6, 7). IgG antibody to dengue virus is detected approximately 14 days after onset in primary infections, and by day 2 in secondary infections. In secondary infections, IgM antibody may reappear but gradually diminishes, while IgG antibody persists, often at high titer. These patterns of dengue antibody development permit serological differentiation of primary and secondary infections. Characteristically, acute patients with primary infections have a higher IgM:IgG ratio than are found in secondary infections. Patients with secondary infections generally have higher IgG levels. Acute or recent infections are identified by a rise in antibody titer as well as high IgM levels (7).

The Flaviviridae family includes the four serotypes of dengue virus as well as the yellow fever and Japanese encephalitis viruses. There is substantial cross reactivity among flaviviruses, due to the presence of common antigenic determinants. The four dengue serotypes cross react among themselves, but there are also unique determinants for each serotype.

Although infection with a given serotype confers durable protection against that serotype, dengue virus serotypes are not cross-protective, and reinfection with a second serotype has been linked to development of the more severe hemorrhagic form of dengue referred to as dengue hemorrhagic fever (1,6).

Determination of the infecting serotype may be important in gauging the potential severity of a dengue outbreak (1). The most straightforward diagnosis of a recent infection is achieved by detection of the virus in patient's blood, either by isolating the virus in susceptible cell cultures or mosquitoes, or by identifying viral RNA with hybridization (6) or PCR (8) techniques. However, these methods are laborious and require specialized laboratory facilities. In addition, the level of circulating virus wanes as the antibody level rises, and these procedures are successful only when done within about 5 days of onset of illness (7,9).

Serological methods to detect dengue antibodies have been the most commonly used diagnostic procedures. The ELISA microwell method for the detection of IgM antibodies is currently the most useful procedure for providing a specific serological diagnosis of dengue infection. This method is reported to be as sensitive as the Hemagglutination
Inhibition (HI) method (7). The IgM ELISA method is generally replacing other techniques for IgM determination because of its sensitivity, potential for automation and ability to accommodate large numbers of samples. For the determination of IgM antibody by the ELISA method, it has been recommended that measures be taken to eliminate IgG antibodies from current or previous flavivirus infections, since IgG antibodies may be present in excess and depress the sensitivity for the detection of IgM (10).

**Assay Principle**

The microwells are coated with purified dengue virus antigen from Vero cell cultured type 1-4 dengue. During the first incubation with the diluted patients’ sera, any antibodies which are reactive with the antigen will bind to the coated wells. After washing to remove the rest of the sample, the Enzyme Conjugate is added. If antibodies have been bound to the wells, the Enzyme Conjugate will then bind to these antibodies. After another series of washes, a chromogen (tetramethlybenzidine, or TMB) is added. If the Enzyme Conjugate is present, the peroxidase will catalyze a reaction that consumes the peroxide and turns the chromogen from clear to blue. Addition of the Stop Solution ends the reaction and turns the blue color to a bright yellow color. The reaction may then be read visually or with an ELISA reader.

**Statement Of Warnings**

**For Export Only**

Do not use solutions if they precipitate or become cloudy. Wash concentrate may show crystallization upon storage at 2-8 °C. Crystallization will disappear after dilution to working strength.

Do not use serum that may have supported microbial growth, or is cloudy due to high lipid content. Samples high in lipids should be clarified before use.

Treat all sera as if capable of being infectious. Controls have been tested and found negative for Hepatitis B surface antigen and for the antibody to HIV by required test methods.

This product should be used under appropriate safety conditions that would be used for any potentially infectious agent.

Do not add azide to any of the kit reagents.

DAI Code # 3
**Storage**

Reagents, strips and bottled components:
- Store between 2 – 8 ºC.
- Squeeze bottle containing diluted wash buffer may be stored at room temperature.

**Specimen Collection And Handling**

DAI Microwell ELISA Dengue Fever test should be performed on serum. Serum may be stored at 2-8 ºC for up to five days. Serum may be frozen below -20 ºC for extended periods. Freezing whole blood samples is not advised.

Single specimens are used to assess exposure; two specimens collected at different times from the same individual are used to show sero-conversion. Paired specimens should be tested at the same time. It is recommended that a convalescent specimen be collected from patients showing either an initially non-reactive result or a weakly reactive result. Due to high cross-reactivity with other flaviviruses, an IgM test is recommended.

**Materials Provided**

DAI MICROWELL ELISA DENGUE KIT

**Materials Required But Not Provided**

- Pipettes
- Squeeze bottle for washing strips (narrow tip is recommended)
- Reagent grade water and graduated cylinder
- Tubes for sample dilution
- Absorbent paper

**Suggested Materials**

- ELISA plate reader with a 450 nm and a 620 - 650 nm filter (optional if results are read visually)

**Procedure**

- Wash Buffer - Remove cap and add contents of bottle to 475 ml of reagent grade water. Place diluted wash buffer into a squeeze bottle with a narrow tip opening.
  - Note: Washings consist of filling to the top of each well, shaking out the contents and refilling.
  - Avoid generating bubbles in the wells during the washing steps.

- Coagulate blood and remove serum. Freeze sample at -20 ºC or lower if not used within 5 days.
- Do not heat inactivate serum and avoid repeated freezing and thawing of samples.

- Test samples: Make a 1:40 dilution of patient’s sera using the dilution buffer (e.g. 10 µl sera and 390 µl dilution buffer).

**Performance Of Tests**

1. Break off number of wells needed (two for controls plus number of samples) and place in strip holder.
2. Add 100 µl (or two drops) of the negative control to well #1, 100 µl of the positive control to well #2 and 100 µl of the diluted (1:40) test samples to the remaining wells.
   - Note: Negative and positive controls are supplied pre-diluted. Do not dilute further.
3. Incubate at room temperature (15 to 25 ºC) for 10 minutes.
4. Shake out contents and wash 3 times with the diluted wash buffer.
5. Add 2 drops of Enzyme Conjugate to each well.
6. Incubate at room temperature for 10 minutes.
7. Shake out contents and wash 3 times with wash buffer.
8. Slap wells against paper towels to remove all liquid.
9. Add 2 drops of the Chromogen to every well.
10. Incubate at room temperature for 5 minutes.
11. Add 2 drops of the Stop Solution and mix by tapping strip holder.
12. Read within one hour of adding Stop Solution.

Reading Results

Visually: Look at each well against a white background (e.g. paper towel) and record as clear or +, ++ or +++ reaction.
ELISA Reader: Zero reader on air. Set for bichromatic readings at 450/620-650 nm.

Quality Control

The use of controls allows validation of kit stability. The kit should not be used if any of the controls are out of range. Expected values for the controls are:
Negative - 0.0 to 0.3 OD units
Positive - 0.5 OD units and above

Troubleshooting

Negative control has excessive color after development.
Reason: inadequate washings
Correction: wash more vigorously. Remove excessive liquid from the wells by tapping against an Absorbent towel. Do not allow test wells to dry out.

Interpretation Of The Test

Initially Non-reactive: Samples interpreted as non-reactive (0.0-0.3 OD units, or zero color) indicate antibody is not present in the sample. Since antibody may not be present during early disease, (5-8 days incubation), confirmation 2-3 weeks later is indicated for laboratory diagnosis. At this later time, patients showing weak reactions (0.5 - ≤1.0 or +, ++) should be further tested by alternate methods or re-tested 10-14 days later. A convalescent serum with a significant reaction (>1.0 OD) indicates the formation of specific antibody against flavivirus. An initially negative result followed by a positive result implies seroconversion.

Initially Weakly Reactive: Weakly reactive specimens should be cautiously interpreted. In normal populations, weakly reactive samples are infrequent but possible. Confirmation using a sample collected 2-3 weeks later (paired acute and convalescent sera), is recommended. >1.0 OD in the second sample confirms the presence of recent, specific antibody. [Caution: If this is a cross-reactive antibody, the convalescent serum sample may not show a higher antibody level than the acute sample.] If sample reading remains at ≥0.5 - ≤1.0 OD, or +, ++, a second methodology (IgM) should be considered, or the sample may be interpreted as taken beyond rising titer (titer declining). If a sample initially reads 0.3 -0.5, diagnosis is indeterminate then a second sample must be drawn. If the second draw is still within the 0.3 - 0.5 range upon repeated testing, the result should be reported as “indeterminate” or an alternate methodology employed.
Initially Reactive: Samples interpreted as strongly reactive (>1.0 OD or +++ or >) may indicate the presence of specific antibody. Antibody presence alone cannot be used for diagnosis of acute infection, since antibodies from prior exposure may circulate for a prolonged period of time.

Limitations Of The Procedure
Diagnosis of dengue infection should not be made solely based on results of the DAI Microwell ELISA Dengue Fever test alone, but in conjunction with other clinical signs and symptoms and other laboratory findings. Epidemiologic factors, clinical findings, exposure to endemic regions, and other laboratory results should be considered when making a diagnosis.

Known cross reactions among dengue antigens must be considered during interpretation, since some epitopes are known to react with other flaviviruses. IgM testing will help to distinguish the cross-reactive samples.

Since serological assay methods may yield different results for weakly reactive samples, a second serological method (i.e. an alternative method that separately identifies IgM and IgG antibody) is recommended.

Expected Values
The number of antibody positive subjects in a population depends on two factors: disease prevalence and clinical criteria used to select the tested population. Because very few positives should be seen in a randomly screened population in a non-endemic area, most serology tests are not specific enough to screen non-endemic populations. Even in an endemic region, serology screening often yields many false positives if used to randomly screen patients. Serology tests are useful to test patients in an endemic region with signs and symptoms consistent with the disease.

Antibody levels are generally low or absent during very early infection. Symptomatic patients may have no antibody during the first 1-2 weeks after exposure and the antibody titer will rise with time.
